The ground state of the two-dimensional three-band Hubbard model in oxide superconductors is investigated by using the variational Monte Carlo method. The Gutzwiller-projected BCS and spin density wave (SDW) functions are employed in the search for a possible ground state with respect to dependences on electron density. Antiferromagnetic correlations are considerably strong near half-filling. It is shown that the $d$-wave state may exist away from half-filling for both the hole and electron doping cases. The overall structure of the phase diagram obtained by our calculations qualitatively agrees with experimental indications. The superconducting condensation energy is in reasonable agreement with the experimental value obtained from specific heat and critical magnetic field measurements for optimally doped samples. The inhomogeneous SDW state is also examined near 1/8 doping. Incommensurate magnetic structures become stable due to hole doping in the underdoped region, where the transfer $t_{pp}$ between oxygen orbitals plays an important role in determining a stable stripe structure.

I. INTRODUCTION

In order to investigate the mechanism of superconductivity (SC) in cuprate high-$T_c$ superconductors,1 we examine the ground state of the two-dimensional (2D) three-band Hubbard model for CuO$_2$ planes which are contained commonly in their crystal structures. It is believed that the CuO$_2$ plane contains the essential features of high-$T_c$ cuprates.2–4 It is not an easy task to clarify the ground-state properties of the 2D three-band Hubbard model because of strong correlations among $d$ and $p$ electrons. We must treat the strong correlations properly to understand the phase diagram of the high-$T_c$ cuprates. The quantum variational Monte Carlo (VMC) method is a tool to investigate the overall structure of the phase diagram from weak to strong correlation regions. In this paper we investigate possible ground states in the three-band Hubbard model for CuO$_2$ plane by employing the VMC method.

Superconductivity in the one-band Hubbard model has been studied by numerical4–13 and analytical14–19 calculations. The three-band Hubbard model has also been investigated with intensive efforts recently.20–29 The exact diagonalization computations for the three-band model in early stage of high-$T_c$ research supported the possibility of superconductivity by showing that holes can bind in small systems.30,31 It is also reported that the attractive interaction works for both the $d$-wave and extended-$s$ wave channels based on finite-temperature quantum Monte Carlo (QMC) simulations.21 It has been shown recently that one can predict finite $T_c$ for the three-band Hubbard model based on perturbative calculations such as generalized random phase approximation (RPA) treatments.26–28 In perturbative treatments of the one-band and three-band Hubbard models, the spin fluctuations induced by the on-site Coulomb interaction promote anisotropic pairing correlations. QMC evaluations with some constraints due to the fermion sign problem are against a possibility of superconductivity in the three-band Hubbard model.25

In order to investigate the possibility and origin of superconductivity, the recent work by Kondo is important where it has been shown that the $d$-wave state has lower energy than the normal state for small $U$ by employing the perturbation theory in $U$ for the one-band Hubbard model.32 This indicates that the ground state is superconductive with $d$-wave symmetry for small values of $U$. We can expect that this also holds for the three-band model.33 It is then natural to expect that the $d$-wave state is stable for finite $U$ unless there occurs some ordering in the ground state. Among several possible long-range orderings, the antiferromagnetic one should be examined because the state with antiferromagnetic ordering is considerably stable near half-filling. In fact, according to VMC work for the one-band Hubbard model, the antiferromagnetic (AF) energy gain is larger than the SC energy gain by almost two orders of magnitude near half-filling. Then the competition between SC and AF states is very severe for the SC state.12,13 The SC region for the one-band Hubbard model is considerably restricted and the possibility of a pure superconducting state is very small.12 A similar feature has been obtained by VMC evaluations for the $U_d=\infty$ three-band Hubbard model33 where the antiferromagnetic region extends up to 50% doping and the $d$-wave phase exists only in the infinitesimally small region near the boundary of the antiferromagnetic phase. Thus VMC results performed recently are consistent with constrained path QMC calculations25 in the sense that the possibility of a $d$-wave phase for the one-band Hubbard model and $U_d=\infty$ three-band Hubbard model is small at present, although an attractive interaction works for $d$-wave pairing.

We expect that the antiferromagnetic region will shrink for the three-band Hubbard model if we adjust the parameters contained in the model. The parameters of the three-band Hubbard model are given by the Coulomb repulsion $U_d$; energy levels of $p$ electrons, $\epsilon_p$, and $d$ electrons $\epsilon_d$; and transfer between $p$ orbitals given by $t_{pp}$. A purpose of this paper is to investigate the property of the antiferromagnetic state and the competition between antiferromagnetism and...
superconductivity for finite $U_d$ based on the three-band model following the ansatz of Gutzwiller-projected wave functions.

It has also been argued that holes doped in the antiferromagnetically correlated spin systems induce incommensurate spin correlations in the ground state for the one-band Hubbard model and three-band model within the mean-field approximation. In the mean-field treatment the energy scales appear to be extremely large compared to values for real materials. Recent neutron-scattering experiments revealed that incommensurate spin structures developed at low temperatures and at low energies. The static incommensurate structure was reported on LSCO samples: La$_{2-x}$Sr$_x$CuO$_4$, La$_{1.6-x}$Nd$_{0.4}$CuO$_4$, and La$_{2-x}$Sr$_x$NiO$_{4+y}$. Incommensurate magnetic peaks have also been reported for YBa$_2$Cu$_3$O$_7$ by inelastic neutron-scattering experiments. This type of inhomogeneous state may possibly provide a key concept to resolve the anomalous properties of high-$T_c$ cuprates in the underdoped region. We will examine a possible phase of incommensurate states for the three-band Hubbard model by the variational Monte Carlo method.

The paper is organized as follows. In the next section the wave functions are presented. The SC state and uniform spin-density-wave (SDW) state are discussed in Sec. III and a stability of incommensurate state is examined in the subsequent section. A summary is given in the last section.

II. HAMILTONIAN AND WAVE FUNCTIONS

The Hamiltonian is given as

$$H = \epsilon_p \sum_i d_i^\dagger d_i + \epsilon_x \sum_i (p_{i+\hat{x},\sigma}^\dagger p_{i+\hat{x},\sigma} + p_{i+\hat{y},\sigma}^\dagger p_{i+\hat{y},\sigma})$$

$$+ t_d \sum_i [d_i^\dagger (p_{i+\hat{x},\sigma} + p_{i+\hat{y},\sigma}) - p_{i-\hat{x},\sigma} - p_{i-\hat{y},\sigma})]$$

$$+ H.c.] + t_p \sum_i \left[ (p_{i+\hat{y},\sigma}^\dagger + p_{i+\hat{x},\sigma}^\dagger) - p_{i-\hat{y},\sigma}^\dagger - p_{i-\hat{x},\sigma}^\dagger \right]$$

$$- t_{\sigma} \sum_i d_i^\dagger d_i d_i^\dagger d_i^\dagger H_0 + \mathcal{V},$$

where

$$\mathcal{V} = U_d \sum_i d_i^\dagger d_i^\dagger d_i^\dagger d_i^\dagger.$$

$x$ and $y$ represent unit vectors along the $x$ and $y$ directions, respectively. $p_{\pm \hat{x},\sigma}^\dagger$ and $p_{\pm \hat{y},\sigma}^\dagger$ denote the operators for the $p$ electrons at site $R_{\pm \hat{x}}$. Similarly $p_{\pm \hat{y},\sigma}^\dagger$ and $p_{\pm \hat{y},\sigma}^\dagger$ are defined. Other notation is standard and energies are measured in units of $t_{dp}$. For simplicity we neglect the Coulomb interaction among $p$ electrons.

We consider the normal-state, BCS, and SDW wave functions. These types of functions are standard wave functions and well describe the ground-state properties with several long-range orderings. They have been investigated intensively for the one-band Hubbard model. In Refs. 51 and 55 it has been discussed that they can be improved systematically by operating correlation factors $e^{-\lambda H_0 e^{-\alpha}V}$. For the model shown above they are written as

$$\psi_n = P_G \prod_{|k|<k_F,\sigma} \alpha_{k,\sigma}^\dagger |0\rangle,$$

$$\psi_{SC} = P_G \prod_k \sum_{\alpha} (u_k + v_k \alpha_{k,\alpha}^\dagger \alpha_{-k,\alpha}^\dagger) |0\rangle,$$

$$\psi_{SDW} = P_G \prod_{|k|<k_F,\sigma} \beta_{k,\sigma}^\dagger |0\rangle,$$

where $\alpha_{k,\sigma}$ is the linear combination of $d_{k,\sigma}$, $p_{k,\sigma}$, and $p_{k,\sigma}$ constructed to express an operator for the lowest band of a noninteracting Hamiltonian in the hole picture. For $t_{pp} = 0$, $\alpha_{k,\sigma}$ is expressed in terms of a variational parameter $\bar{\epsilon}_p - \epsilon_d$:

$$\alpha_{k,\sigma}^\dagger = \left[ 1 + \frac{\bar{\epsilon}_p - \epsilon_d}{2E_k} \right]^{1/2} d_{k,\sigma}^\dagger$$

$$+ \frac{1}{2} \left[ 1 - \frac{\bar{\epsilon}_p - \epsilon_d}{2E_k} \right]^{1/2} \left( \frac{w_{ik}}{w_k} p_{ik,\sigma}^\dagger + \frac{w_{ik}}{w_k} p_{ik,\sigma} \right),$$

where $w_{ik} = 2t_d \sin(k \hat{x}), \ w_{ik} = 2t_d \sin(k \hat{y}), \ w_k = (w_{ik}^2 + w_{ik}^2)^{1/2}$, and $E_k = [(\bar{\epsilon}_p - \epsilon_d)^2/4 + w_k^2]^{1/2}$. The Fourier transforms of $d$- and $p$-electron operators are defined as

$$d_{k,\sigma}^\dagger = \frac{1}{N^{1/2}} \sum_i d_i^\dagger e^{iNk \cdot R_i},$$

$$p_{k,\sigma}^\dagger = \frac{1}{N^{1/2}} \sum_i p_i^\dagger e^{iNk \cdot R_i + i\hat{y}},$$

$$p_{k,\sigma}^\dagger = \frac{1}{N^{1/2}} \sum_i p_i^\dagger e^{iNk \cdot R_i + i\hat{x}},$$

where $N$ is the total number of cells which consist of $d$, $p_x$, and $p_y$ orbitals. Coefficients $u_k$ and $v_k$, appearing only as a ratio, are given by the BCS form

$$\frac{u_k}{\xi_k} = \frac{\Delta_k}{\xi_k + (\xi_k^2 + \Delta_k^2)^{1/2}}.$$

for $\xi_k = \epsilon_k - \mu$, where $\epsilon_k$ is the energy dispersion for the lowest band. $P_G$ is the Gutzwiller projection operator for the Cu $d$ site and $P_{N_k}$ is a projection operator which extracts only the states with a fixed total electron number. The SC order parameter $\Delta_k$ is assumed to have the following $\Delta_{z^2-r^2}$ and extended $s$-wave form:

$$d: \ \Delta_k = \Delta_s (\cos k_x - \cos k_y),$$

184509-2
\[ s^p: \quad \Delta_k = \Delta_s (\cos k_x + \cos k_y). \] (12)

Equation (4) is written as
\[ \psi_{SC} = P_G \left( \sum_k \frac{v_k}{u_k} \alpha_k^+ \alpha_{-k}^\dagger \right) N_{c/2}. \] (13)

The wave function given by Eq. (13) agrees with
\[ \psi_{BCS} = P_G \prod_k (u_k + v_k \alpha_k^+ \alpha_{-k}^\dagger) |0\rangle \] (14)
in the thermodynamic limit. For the commensurate SDW state \( \beta_{k_0} \) is given by a linear combination of two wave numbers \( \mathbf{k} \) and \( \mathbf{k} + \mathbf{Q} \) for the commensurate vector \( \mathbf{Q} = (\pi, \pi) \). We can also investigate the incommensurate SDW state with incommensurate vector \( \mathbf{Q} = (\pi + 2 \pi \delta, \pi) \) by diagonalizing the Hartree-Fock Hamiltonian with antiferromagnetic long-range order. The system sizes are given by \( 6 \times 6 \) and \( 8 \times 8 \) for the projected BCS wave function and \( 16 \times 4, 24 \times 6, 32 \times 8, 40 \times 10, \) and \( 16 \times 16 \) for the incommensurate SDW states. Our calculations are performed with periodic and antiperiodic boundary conditions for the \( x \) and \( y \) directions, respectively. This set of boundary conditions was chosen so that \( \Delta_k \) does not vanish for any \( \mathbf{k} \) points possibly occupied by electrons.

The expectation values are calculated following the standard Monte Carlo procedure by using the Metropolis algorithm. In the process of finding a minimum of energy, we should optimize many parameters included in the wave functions. For such a purpose we employ correlated measurements method to reduce the required CPU time.\(^{36}\)

III. CONDENSATION ENERGY AND PHASE DIAGRAM

First, let us discuss the SDW phase near half-filling by evaluating the ground-state energy for optimized parameters \( g \) and \( \epsilon_p - \epsilon_d \) and AF order parameter \( \Delta_{AF} \). We set \( \epsilon_p = 0 \) throughout this paper. It is expected that holes introduced by doping are responsible for the disappearance of long-range antiferromagnetic ordering.\(^{37,38}\) We show the SDW energy gain \( \Delta E_{SDW} \) in Fig. 1 as a function of doping ratio for several values of \( \epsilon_p - \epsilon_d \). \( \Delta E_{SDW} \) increases and the SDW region becomes larger as \( \epsilon_p - \epsilon_d \) increases. Figure 2 shows the SDW energy gain for several values of \( t_{pp} \), where \( \Delta E_{SDW} \) is reduced as \( t_{pp} \) increases. In Figs. 3(a) and 3(b) the dependence on Coulomb repulsion \( U_d \) is shown; the SDW phase extends up to 30\% doping when \( U_d \) is large. Then it follows that the SDW region will be reduced if \( \epsilon_p - \epsilon_d \) and \( U_d \) decrease or \( t_{pp} \) increases. In fact, Fig. 4 shows the boundary of the SDW phase in the \( t_{pp}-\delta \) plane for \( U_d = 8 \) where \( \delta \) is the hole density and negative density indicates electron doping. Compared to the calculations for \( U_d = \infty \) the SDW region is reduced greatly.\(^{33}\)

Next, let us turn to the projected-BCS wave function, where the Gutzwiller parameter \( g \), effective level difference \( \tilde{\epsilon}_p - \tilde{\epsilon}_d \), chemical potential \( \mu \), and superconducting order parameter \( \Delta_s \) are considered as variational parameters. In Fig. 5 we show the energy as a function of \( \Delta_s \) where \( t_{pp} = 0.0, \)

\[ U_d = 8, \] and \( \epsilon_d - \epsilon_p = 2 \) and the doping ratio is given by \( \delta = 0.111 \) for (a) and \( \delta = 0.333 \) for (b). The \( d \)-wave superconductivity is most stable among various possible states such as isotropic \( s \)-wave and anisotropic \( s \)-wave pairing states. The squares in Fig. 5 denote the values for the normal state, which are estimated independently by using an alternative Monte Carlo algorithm. The finite SC energy gain indicates that the attractive interaction works for \( d \)-wave pairing.

The SC energy gain (which is called the SC condensation energy in this paper) is also dependent on \( \epsilon_p - \epsilon_d \), as is

\[ U_d = 8, \] and \( \epsilon_d - \epsilon_p = 2 \) and the doping ratio is given by \( \delta = 0.111 \) for (a) and \( \delta = 0.333 \) for (b). The \( d \)-wave superconductivity is most stable among various possible states such as isotropic \( s \)-wave and anisotropic \( s \)-wave pairing states. The squares in Fig. 5 denote the values for the normal state, which are estimated independently by using an alternative Monte Carlo algorithm. The finite SC energy gain indicates that the attractive interaction works for \( d \)-wave pairing.

The SC energy gain (which is called the SC condensation energy in this paper) is also dependent on \( \epsilon_p - \epsilon_d \), as is
shown in Fig. 6 for $t_{pp}=0.2$, $U_d=8$, and $\delta=0.111$ on a 6\times6 lattice. This shows a tendency that the SC condensation energy increases as $\epsilon_p-\epsilon_d$ increases, which is consistent with calculations for $U_d=\infty$.\textsuperscript{33} It is noted that the dependence on $\epsilon_p-\epsilon_d$ for the SC energy gain is rather weak compared to the SDW energy gain. We also note that the SC energy gains for $U_d=8$ are mostly of the same order of those for $U_d=\infty$.\textsuperscript{33}

From the calculations for the SDW wave functions, we set $\epsilon_p-\epsilon_d$ and $U_d$ small so that the SDW phase does not occupy a huge region near half-filling. In Fig. 7 we show energy gains for both the SDW and SC states for $U_d=8$, $t_{pp}=0.2$, and $\epsilon_p-\epsilon_d=2$, where the negative $\delta$ indicates the electron-doping case. Solid symbols indicate the results for $8\times8$ and open symbols for $6\times6$. For this set of parameters the SDW region extends up to 20\% doping and the pure $d$-wave phase exists outside of the SDW phase. The $d$-wave phase may be possibly identified with the superconducting phase in the overdoped region in the high-$T_c$ superconductors.

The superconducting condensation energy obtained by
measurements for optimally doped samples. They are given
several experiments such as specific heat or critical field
value is in reasonable agreement with the experimental data
cluster calculations. 60– 62 We have also estimated
t_{dp}
vertical axis, where we set

eV as estimated from cluster calculations. 60– 62 We have also estimated
E_{cond}
from several experiments such as specific heat or critical field
measurements for optimally doped samples. They are given
as
0.17=0.26
meV from specific heat data 12,63,64 and 0.26
meV from the critical magnetic field value
H_c
5
0.59
meV/site. 54 This agreement between the theoretical
and experimental condensation energy is highly remarkable.
We expect that this value is not far from the correct value
according to the evaluations for improved wave functions, 51
where it was shown that the energy gain is not changed so
much due to multiplicative correlation factors
e^{-\Delta \pi \hbar \omega_c - \Delta \hbar \pi}. We cannot estimate the SC condensation energy in the
underdoped region because the SDW state is more stable than
the d-wave state and the SC condensation energy is not avail-
able experimentally due to a loss of entropy in the under-
doped region. 53

The phase structure obtained by our calculations agrees
well with the available phase diagram indicated by experi-
ments qualitatively, which means that a large SDW phase
exists in the underdoped region and there is a d-wave super-
conducting phase next to the SDW phase in the overdoped
region. Our calculations for the electron-doping case predict
d-wave symmetry away from half-filling, which is consistent
with recent experiments on Nd_{1.85}Ce_{0.15}CuO_{4-\delta}. 66

IV. INCOMMENSURATE ANTIFERROMAGNETISM WITH
SPIN MODULATION

In this section let us discuss the underdoped region where
the SDW state is significantly stable as shown in the previous
section. Let us note that the SDW state can be possibly stabilization further if we take into account a spin modulation in space, as has also been studied for the one-band Hubbard
model 35– 40, 67 and the t-J model 68– 71 We can introduce a stripe in the uniform spin-density state so that doped holes
occupy new levels close to the starting Fermi energy, keep-
ing the energy loss of antiferromagnetic background mini-
mum. The wave function with a stripe can be taken of the
Gutzwiller type:
ψ_{stripe}=P_Gψ_{stripe}^0. Here ψ_{stripe}^0 is the
Slater determinant made from solutions of the Hartree-Fock
Hamiltonian 67

\begin{equation}
H_{stripe}=H_{dp}^0+\sum_{i\sigma} \left[ \langle \bar{n}_{di} \rangle - \sigma (-1)^{x_i+y_i} \langle m_i \rangle \right] d_i^\dagger d_i^\sigma ,
\end{equation}

where
H_{dp}^0
is the noninteracting part of the Hamiltonian
H
with variational parameter
\bar{\epsilon}_p-\bar{\epsilon}_d.
\langle \bar{n}_{di} \rangle \ and \ \langle m_i \rangle \ are expressed in terms of modulation vectors
Q_s
and
Q_c
for spin
and charge part, respectively. Including the constant part of
\langle \bar{n}_{di} \rangle \ in the definition of variational parameter
\bar{\epsilon}_d,
we diagonalize the following one-particle Hamiltonian to determine
ψ_{stripe}^0:

\begin{equation}
H_{stripe}=H_{dp}^0+\sum_{i\sigma} \left[ \delta n_{di} - \sigma (-1)^{x_i+y_i} m_i \right] d_i^\dagger d_i^\sigma .
\end{equation}

(16)

δn_{di} \ and \ m_i \ are assumed to have the form

\begin{equation}
\delta n_{di}=-\sum_j \alpha/\cosh((x_i-x_j^\infty)/\xi_c),
\end{equation}

(17)
with parameters $\alpha$, $m$, $\xi_c$, and $\xi_s$. Here $x_j^{\text{str}}$ denotes the position of a stripe. In actual calculations we set $\xi_c = 1$ and $\xi_s = 1$ since the energy expectation values are mostly independent of $\xi_c$ and $\xi_s$. Since any eigenfunction of the Hamiltonian $H_{dp}$ can be a variational wave function, we optimize $\alpha$ instead of fixing it in order to lower the energy expectation value further. It is also possible to assume that $\delta n_{d_0}$ and $m_i$ oscillate according to the cosine curve given as $\cos(4\pi \delta x_i)$ and $\cos(2\pi \delta y_i)$, respectively. Both methods give almost the same results within Monte Carlo statistical errors.

Recent neutron-scattering experiments suggested that modulation vectors are given by $Q_s = (\pi \pm 2\pi \delta, \pi)$ and $Q_c = (\pi \pm 2\pi \delta, 0)$ in the underdoped region, where $\delta$ denotes the doping ratio. Here we define $n$-lattice stripe as an incommensurate state with one stripe per $n$ ladders for which $Q_s$ is given by $Q_s = (\pi \pm \pi/n, \pi)$. Then the incommensurate state predicted by neutron experiments for $\delta = 1/8$ is given by a four-lattice stripe. For the three-band model, the transfer $t_{pp}$ between oxygen orbitals plays an important role to determine a possible SDW state. If $t_{pp}$ is very large, the uniform SDW state is expected to be stabilized because holes doped on oxygen sites can move around on the lattice, producing disorder effects on spin ordering uniformly. For small $t_{pp}$ the stripe states are considered to be realized. 41 Our motivation to consider nonuniform states for the three-band model lies in the idea that the distance between stripes may be dependent upon $t_{pp}$; i.e., for small $t_{pp}$ the distance between stripes is large, for intermediate values of $t_{pp}$ the four-lattice stripe state is realized, and for large $t_{pp}$ the uniform state or normal state is stable.

In Fig. 8 we show the energies for commensurate and incommensurate SDW states on a $16 \times 4$ lattice at $\delta = 1/8$ for $U_d = 8$. Circles and triangles are for four-lattice and eight-lattice stripes, respectively. Squares denote energy for the commensurate SDW state. From the top $\epsilon_p - \epsilon_d = 1.2$, 2.0, and 2.4. We impose antiperiodic boundary conditions in the $x$ direction and periodic boundary conditions in the $y$ direction.

$$(m_i = m \prod_j \tanh[(x_i - x_j^{\text{str}})/\xi_s], \quad (18)$$

with parameters $\alpha$, $m$, $\xi_c$, and $\xi_s$. Here $x_j^{\text{str}}$ denotes the position of a stripe. In actual calculations we set $\xi_c = 1$ and $\xi_s = 1$ since the energy expectation values are mostly independent of $\xi_c$ and $\xi_s$. Since any eigenfunction of the Hamiltonian $H_{dp}$ can be a variational wave function, we optimize $\alpha$ instead of fixing it in order to lower the energy expectation value further. It is also possible to assume that $\delta n_{d_0}$ and $m_i$ oscillate according to the cosine curve given as $\cos(4\pi \delta x_i)$ and $\cos(2\pi \delta y_i)$, respectively. Both methods give almost the same results within Monte Carlo statistical errors.

Recent neutron-scattering experiments suggested that modulation vectors are given by $Q_s = (\pi \pm 2\pi \delta, \pi)$ and $Q_c = (\pi \pm 2\pi \delta, 0)$ in the underdoped region, where $\delta$ denotes the doping ratio. Here we define $n$-lattice stripe as an incommensurate state with one stripe per $n$ ladders for which $Q_s$ is given by $Q_s = (\pi \pm \pi/n, \pi)$. Then the incommensurate state predicted by neutron experiments for $\delta = 1/8$ is given by a four-lattice stripe. For the three-band model, the transfer $t_{pp}$ between oxygen orbitals plays an important role to determine a possible SDW state. If $t_{pp}$ is very large, the uniform SDW state is expected to be stabilized because holes doped on oxygen sites can move around on the lattice, producing disorder effects on spin ordering uniformly. For small $t_{pp}$ the stripe states are considered to be realized. 41 Our motivation to consider nonuniform states for the three-band model lies in the idea that the distance between stripes may be dependent upon $t_{pp}$; i.e., for small $t_{pp}$ the distance between stripes is large, for intermediate values of $t_{pp}$ the four-lattice stripe state is realized, and for large $t_{pp}$ the uniform state or normal state is stable.

In Fig. 8 we show the energies for commensurate and incommensurate SDW states on a $16 \times 4$ lattice at $\delta = 1/8$ as a function of $t_{pp}$, where we impose antiperiodic and periodic boundary conditions in the $x$ and $y$ directions, respectively, so that the closed-shell structure is followed for doped holes. We assumed that $\epsilon_p - \epsilon_d = 1.2$, 2, and 2.4. The eight-lattice stripe state for small $t_{pp}$ changes into a uniform state as $t_{pp}$ increases. It shows that incommensurate states become stable for a large level difference $\epsilon_p - \epsilon_d$. The spin and charge densities of the incommensurate state are shown in Fig. 9 for $t_{pp} = 0.4$ and $\epsilon_p - \epsilon_d = 2$ where the charge density is a sum of hole numbers on $d$, $p_x$, and $p_y$ orbitals at site $L$. The spin density $S_z(i) = n_{d_i} - n_{d_i^\dagger}$ vanishes at the positions of stripes associated with peaks of the hole density. The spin structure factor $S_z(Q)$ really has incommensurate peaks as is shown in Fig. 10. Figures 11(a) and 11(b) present the energies of incommensurate states for $16 \times 16$ lattice (which contains 768 atoms) where we set antiperiodic and periodic boundary conditions in the $x$ and $y$ direction, respectively, for (a) and in the $y$ and $x$ directions, respectively, for (b). Both figures give almost the same results as evidence that the effect of bound-
ary conditions is small for a 16\times 16 system. As expected, the structure of the incommensurate state is dependent upon the values of $t_{pp}$.

Let us turn to a discussion of the energy gain due to a formation of stripes, which is estimated from an extrapolation to the bulk limit as shown in Fig. 12. One notes that the energy gain increases as the system size increases. The energy gain per site for a four-lattice stripe state is given by $0.015t_{dp}$. Furthermore, the energy difference between commensurate and incommensurate states is found to be finite in the bulk limit, which is shown in Fig. 13. Thus within the VMC method the stripe state with spin modulation is stable at $\delta = 1/8$ doping.

The antiferromagnetic order parameter $m$ in Eq. (18) is of the order of $0.5t_{dp} = 0.75$ meV, while the SC order parameter $\Delta$ (which gives the minimum of energy) is of the order of $(0.01-0.015)t_{dp} = 15-20$ meV at $\delta = 0.2$. The magnitude of the SC order parameter agrees with measurements of tunneling spectroscopy\textsuperscript{72,73} where $\Delta_{c}$ is estimated as $\Delta_{c} = 17$ meV for a YBCO sample.\textsuperscript{72} The antiferromagnetic order parameter is larger than the SC order parameter at least by one order of magnitude. The charge order parameter $\alpha$ in Eq. (17) is small and negligible compared to $m$.

V. SUMMARY

We have presented our evaluations for the 2D three-band Hubbard model based on the variational Monte Carlo method. Our work is regarded as a starting step for more sophisticated calculations in the future such as the inclusion of correlation factors of Jastrow type or Green function Monte Carlo approaches. The SC energy scales obtained from our evaluations are consistent with experimental indications, which provides support to our approaches.

According to the VMC method the attractive interaction works for $d$-wave pairing due to electron correlations. The strength of $U_{d}$ is also important to determine the phase boundary of the SDW phase. If $U_{d}$ is extremely large, the SDW region extends up to large doping for which the $d$-wave region is restricted to an infinitesimally small region near the boundary of the antiferromagnetic phase. For intermediate values of $U_{d}$ and $\epsilon_{p} - \epsilon_{d}$ the SDW region is reduced and the $d$-wave superconducting phase may exist. The fact that the SC condensation energy agrees reasonably with the experimental data for optimally doped samples supports our computations. The magnitude of the SC order parameter is also consistent with tunneling spectroscopy experiments. From our data for $\Delta E_{SC}$ and $\Delta_{c}$ and the relation $N(0)\Delta_{c}^{2}/2 = \Delta E_{SC}$, the effective density of state $N(0)$ can be estimated as $N(0) \approx 3-6.7$ (eV)$^{-1}$ \textsuperscript{4.4} by using $N(0)(k_{B}T_{c})^{2}/2$ for optimally doped YBCO.\textsuperscript{64} We expect that the pure $d$-wave state from optimal to overdoped regions may be described by the projected-BCS wave function. The phase diagram for electron doping is consistent with the available experimental...
indications suggesting that the properties of electron-doped materials may be understood within our approach. In the SDW region the incommensurate spin structures are stabilized for the low-doping case to keep the energy loss minimum due to disorder effect caused by holes. Competition among the uniform SDW state, SDW state with stripes, and pure d-wave SC is highly nontrivial. A picture for the hole-doping case followed from our evaluations is that a stripe state is stable in the underdoped region and changes into d-wave SC in the overdoped region.
